Studies have continued on the chemistry and pharmacology of several venomous fishes, some of the problems relating to their habitats in relation to man, and more definitive investigations on the usual ultracellular structure of their venom glands. The present report treats of our most recent study on the venom gland of the sting-ray Dasyatis sabina.

The fine structure of the putative venom-secreting cells within the tissue sheath investing the spine are unique in possessing large membrane-limited vacuoles (ca. 10  $\mu$  diameter), each largely filled (in thin sections) with 50,000 or more profiles of structures resembling cytoplasmic microtubules in size (ca. 200 $\text{\AA}$  diameter) and appearance, in an electron-lucent matrix. It has previously been proposed that these vacuoles may include the secreted venom in a terminally differentiated cell.

These "microtubules" differ from the well-documented tubulin polymers (conventional microtubules) in four important respects: (1) they are sequestered from the general cytoplasm within a membrane; (2) they are curved within the spheroidal vacuole unlike conventional microtubules which are typically linear; (3) previous results suggest that, unlike many cytoplasmic microtubules, these structures are not depolymerized by vinblastin; and (4) the array includes many contiguous pairs and groups lacking the intervening space invariably present between juxtaposed cytoplasmic microtubules. Furthermore, the situation of these structures rules out the two principal functions ascribed to tubulin microtubules (translocation of membrane-limited and other particulates within the cytoplasm and provision of a cytoskeletal framework in elongated cells and cell processes). Electrophoretic studies are in progress designed to establish whether the microtubular structures are a new category of tubulin polymers or represent another protein that polymerizes in a structurally similar manner.
